1 Problem 1

1.1 (a)

Without loss of generality, assume x > y for $x, y \in \mathbb{Z}^+$. The loop invariant is:

$$Euclidean(x,y) = Euclidean(x-y,y) \tag{1}$$

1.2 (b)

Without loss of generality, assume x > y for $x, y \in \mathbb{Z}^+$.

Let d for $d \in \mathbb{Z}^+$ being the greatest common divisor of x and y, a.k.a d = gcd(x, y). As d being a divisor of both x and y, we may therefore have x = kd and y = jd for $k, j \in \mathbb{Z}^+$. Then we may infer:

$$x - y = dk - dj = d(k - j)$$
(2)

From Equation 2 and the known fact that y = jd, we may say that d is also a common divisor of x - y and y. By the defination of gcd, this means the upper bond of d cannot be greater than gcd(x - y, y). Thus we may conclude:

$$gcd(x,y) = d \le gcd(x-y,y)$$

$$\Rightarrow gcd(x,y) \le gcd(x-y,y)$$
(3)

Now similarly, Let e for $e \in \mathbb{Z}^+$ being the greatest common divisor of x-y and y. We may therefore have x-y=le and y=me for $l,m\in\mathbb{Z}^+$. Then we may infer:

$$x = (x - y) + y = le + me = e(l + m)$$
 (4)

From Equation 4 and the known fact that y = me, we may say that e is also a common divisor of x and y. By the defination of gcd, this means the upper bond of e cannot be greater than gcd(x,y). Thus we may conclude:

$$gcd(x - y, y) = e \le gcd(x, y)$$

$$\Rightarrow gcd(x - y, y) \le gcd(x, y)$$
(5)

By observing Equation 3 and Equation 5, we may have a constraint of gcd(x, y) = gcd(x - y, y). As the given method Euclidean() is a gcd finder, we may promote such constraint to Euclidean(x, y) = Euclidean(x - y, y) due to the equivalency of Euclidean(a, b) and gcd(a, b).

1.3 (c)

The while loop always terminates as the condition x = y will eventually be reached. Due to the fact that we have x and y for $x, y \in \mathbb{Z}^+$; without loss of generality, we assume x > y, therefore we must have x' = x - y for $x' \in \mathbb{Z}^+$.

As we have only a finte amount of x', x'', x'''... to decrease for x', x'', and $x''' \in \mathbb{Z}^+$, the decremental calculation of $x_{k+1} = x_k - y_k^1$ will eventually reaches a condition where x = y due to the "well ordering" nature of the natural numbers. Thus, the while loop always terminates.

1.4 (d)

In **Section 1.2**, we have proven that $gcd(x,y) = gcd(x-y,y) \Rightarrow Euclidean(x,y) = Euclidean(x-y,y)$ assuming x > y for $x,y \in \mathbb{Z}^+$. Following the principle of induction, we can generalize it as:

$$Euclidean(x,y) = Euclidean(x_{k+1}, y_{k+1})$$
for $x', y' \in \mathbb{Z}^+$ while
$$x_{k+1} = x_k - y_k \text{ if } x_k > y_k \text{ and } y_{k+1} = y_k - x_k \text{ if } y_k > x_k$$
(6)

Where $Euclidean(x_{k+1}, y_{k+1})$ is the greatest common divisor of (x, y).

As we haven proven in **Section 1.2**, that the while loop within the Euclidean() method must terminate. Combined such finding with Equation 6, we must have a:

$$Euclidean(a,b) = Euclidean(a_{k+1}, b_{k+1}) = Euclidean(a_{k+2}, a_{k+2})$$
(7)

 $[\]overline{\ }^{1}$ for k being the numbers of iteration went through in the while loop.

As we know by calculation that $Euclidean(a_{k+2}, a_{k+2}) = a_{k+2}$, a_{k+2} will be the greatest common divisor of Euclidean(a, b).

2 Problem 2

2.1 (a)

Algorithm 1 TwoSum(A, B, n, x) with two pointers

```
1: procedure
 2:
        j \leftarrow n-1
        i \leftarrow 0
 3:
        while i < n and j \ge 0 do
 4:
            if A[i] + B[j] < x then
 5:
                 i \leftarrow i + 1
 6:
            else if A[i] + B[j] > x then
 7:
                 j \leftarrow j - 1
 8:
 9:
            else
                 return i, j
10:
        return False
11:
```

2.2 (b)

2.3 (c)

If $A[i] + B[j] \neq x$, then it is impossible to have any combination (a, b) where $a \in \{A[0], A[1], ..., A[i-1], A[i]\}$ and $b \in \{B[j], B[j+1], B[j+2], ..., B[n-1]\}$ to be a + b = x for all **iterarted** i, j within the while loop.

Assume we get A[i] + B[j] = k within an interation of the while loop, we either have k < x or k > x (assume $A[i] + B[j] \neq x$ because otherwise the loop will be terminated and the problem will be solved). Due to the sorted nature of array A, B, we must have:

$$\underbrace{A[0] \le A[1] \le \dots \le A[i-1]}_{a} \le A[i] \quad \Rightarrow a \le A[i] \tag{8}$$

$$\underbrace{B[n-1] \ge \dots \ge B[j+2] \ge B[j+1]}_{b} \ge B[j] \quad \Rightarrow b \ge B[j] \tag{9}$$

Thus, we may infer the followings from the above two *Equations*:

if
$$k < x : a + B[j] \le A[i] + B[j] \implies a + B[j] < x$$
 (10)

if
$$k > x$$
: $A[i] + b \ge A[i] + B[j] \implies A[i] + b > x$ (11)

It is a bit unintuitive about the case of a' + b' for $a' \in \{A[0], A[1], ..., A[i-1]\}$ and $b' \in \{B[j+1], B[j+2], ..., B[n-1]\}$. But as the value of index i (j) travels in an incremental (decremental) fashion in the bond of $Z+ \in [0,n)$; the index of a' must be smaller than i, and the index of b' must be greater than j. Thus, if there is any a' + b' = x, such loop would have been terminated immediately and we should not be able to reach to indexes i, j in the while loop. Therefore, as we are now at the i, j iteration of the while loop, this suggests there is no (a', b') combination where a' + b' = x.

This together with Equation 10, 11, we have proven the loop invariant as there will be no combination of (a,b) where $a \in \{A[0],A[1],...,A[i-1],A[i]\}$ and $b \in \{B[j],B[j+1],B[j+2],...,B[n-1]\}$ to be a+b=x for all **iterarted** i,j within the while loop.

2.4 (d)

The worst case of this algorithm is when it returns False. In such case we wil have i and j travel the entire bond of $Z+ \in [0,n)$. The loop will execute 2n times, thus the run time is O(n).

3 Problem 3
